(Dated: February 6, 2008)

Using computer simulations of over 100,000 atoms, the mechanism for the hydrophobic collapse of an idealized hydrated chain is obtained. This is done by coarse-graining the atomistic water molecule positions over 129,000 collective variables that represent the water density field and then using the string method in these variables to compute the minimum free energy pathway (MFEP) for the collapsing chain. The dynamical relevance of the MFEP (i.e. its coincidence with the mechanism of collapse) is validated *a posteriori* using conventional molecular dynamics trajectories. Analysis of the MFEP provides atomistic confirmation for the mechanism of hydrophobic collapse proposed by ten Wolde and Chandler. In particular, it is shown that lengthscale-dependent hydrophobic dewetting is the rate-limiting step in the hydrophobic collapse of the considered chain.

I. INTRODUCTION

This paper applies the string method^{1,2,3} to the phenomenon of hydrophobic collapse. It is shown that the method can describe complex dynamics in large atomistic systems, ones for which other currently available rare event methods would seem intractable. Furthermore, the string method is used to demonstrate that atomistic dynamics can be usefully projected onto that of a coarse-grained field. The specific application of the string method considered herein finds results that are consistent with the mechanism of hydrophobic collapse put forward by ten Wolde and Chandler.⁴

The hydrophobic effect - or the tendency of oil and water to separate on mesoscopic lengthscales - has long been recognized as an important driving force in molecular assembly.⁵ It stabilizes the formation of micelles, protein tertiary structure, multi-protein assemblies, and cellular membranes.^{6,7} Recent theoretical developments have helped establish a quantitative understanding of the thermodynamics of hydrophobicity,^{8,9} but the dynamics of hydrophobic collapse remain poorly understood because it couples a large range of length- and timescales. Relevant processes include the atomic-scale motions of individual water molecules, collective solvent density fluctuations, and the nanometer-scale movements of the hydrophobic solutes. Bridging these dynamical hierarchies - and addressing the problem of complex dynamics in large systems - is a fundamental challenge for computational methods.

We address this challenge using the string method in collective variables.^{1,2,3} We consider the collapse of a chain composed of twelve spherical hydrophobes in an explicit solvent of approximately 34,000 water molecules. The system is studied by coarse-graining the water molecule positions onto a set of 129,000 collective variables that represent the solvent density field and then using the string method in these variables to compute the minimum free energy path (MFEP) for the hydrophobic collapse of the chain. Conventional molecular dynamics

(MD) simulations are subsequently performed to confirm that this coarse-grained description adequately describes the mechanism of hydrophobic collapse.

ten Wolde and Chandler⁴ have previously reported simulations of a non-atomistic model for the hydrated chain considered herein. It was found that the key step in the collapse dynamics is a collective solvent density fluctuation that is nucleated at the hydrophobic surface of the chain. However, it was not clear whether this proposed mechanism captured the essential features of hydrophobic collapse or whether it was an artifact of the model. Atomistic simulations were needed to resolve the issue.

Previous efforts to characterize the mechanism of hydrophobic collapse using atomistic computer simulations neither confirm nor disprove the mechanism proposed by ten Wolde and Chandler. In recent work, for example, molecular dynamics (MD) simulations showed that dewetting accompanies the collapse of hydrophobes in water.^{10,11,12,13} However, the rate-limiting step - and thus the mechanism for hydrophobic collapse - was not characterized. Specifically, in Ref. 12, MD trajectories were initiated at various separation distances for a pair of meletin protein dimers. Observation of the collapse dynamics was observed only when the initial configuration was on the “near” side of the free energy barrier, but the actual nature of that barrier - and the dynamics of crossing it - were not studied. In Ref. 13, the thermodynamics and solvation of a hydrophobic chain was studied as a function of its radius of gyration, but again, the dynamics of collapse was not characterized.

The results presented here are the first atomistic simulations to explicitly confirm the mechanism of hydrophobic collapse put forward by ten Wolde and Chandler.⁴ In particular, we show that the rate-limiting step in hydrophobic collapse coincides with a collective solvent motion and that performing the rate-limiting step involves performing work almost exclusively in the solvent coordinates. We further show that the solvation free energy along the MFEP can be decomposed into small- and large-lengthscale contributions. This analy-

sis demonstrates that atomistic solvent energetics can be quantitatively modeled using a grid-based solvent density field, and it suggests that the rate-limiting step for hydrophobic collapse coincides with lengthscale-dependent hydrophobic dewetting.

Combined, the results presented in this study provide (1) evidence that the string method is a powerful tool for atomistically simulating complex dynamics in large systems, (2) a proof of principle that atomistic solvent dynamics can be usefully projected onto that of a coarse-grained field, and (3) an atomistic demonstration that dewetting is key to the dynamics of hydrophobic collapse.

II. ATOMISTIC MODEL, COARSE-GRAINING, AND THE STRING METHOD

A. The system

We consider the atomistic version of the hydrated hydrophobic chain studied by ten Wolde and Chandler.⁴ The chain is composed of twelve spherical hydrophobes, each of diameter 7.2 Å and mass 70 amu. These are ideal hydrophobes, as they exert purely repulsive interactions upon the oxygen atoms of the water molecules. Consecutive hydrophobes in the unbranched chain interact via harmonic bonds, and the chain is made semi-rigid by a potential energy term that penalizes its curvature. The chain is hydrated with approximately 34000 rigid water molecules in an orthorhombic simulation box with periodic boundary conditions. All simulations were performed at 300 K. Full details of the system are provided in the Supporting Information Sec. A.

In describing hydrophobic collapse, it is necessary to choose an appropriate thermodynamic ensemble for the simulations. Nanometer-scale fluctuations in solvent density are suspected to play a key role in these dynamics. Use of the NVT ensemble (with a 1 g/cm³ density of water) might suppress these density fluctuations and bias the calculated mechanism. We avoid this problem with a simple technique that is based on the fact that under ambient conditions, liquid water is very close to phase coexistence. Indeed, it is this proximity that leads to the possibility of large lengthscale hydrophobicity.^{8,17} By placing a fixed number of water molecules at 300 K in a volume that corresponds to an average density of less than 1 g/cm³, we obtain a fraction of the system at the density of water vapor and the majority at a density of bulk water. Since we are not concerned with solvent fluctuations on macroscopic lengthscales, the difference between simulating bulk water at its own vapor pressure compared to atmospheric pressure is completely negligible. This strategy has been previously employed to study the dewetting transition between solvophobic surfaces.^{14,15} To ensure that the liquid-vapor interface remains both flat and well-distanced from the location of the chain, we repel particles from a thin layer at the top edge of the simulation box, as is discussed in Supporting

Information Sec. A.

B. Coarse-graining

Throughout this study, we simulate the hydrated chain using atomistic MD, but we employ the string method using collective variables that describe the solvent density field. A coarse-graining algorithm is developed to connect these atomistic and collective variable representations of the solvent. Following ten Wolde and Chandler,⁴ the simulation box is partitioned into a three-dimensional lattice (48×48×56) of cubic cells with sidelength $l = 2.1$ Å. We label the cells with the vector $\mathbf{k} = (k_x, k_y, k_z)$, where each k_ζ takes on integer values bounded as follows: $1 \leq k_x \leq 48$, $1 \leq k_y \leq 48$, and $1 \leq k_z \leq 56$. On this grid, the molecular density, $\rho(\mathbf{r})$, is coarse grained into the field $P_{\mathbf{k}}$, where

$$P_{\mathbf{k}} = \int d\mathbf{r} \rho(\mathbf{r}) \sum_{\zeta=x,y,z} \Phi_{k_\zeta}(\mathbf{r} \cdot \mathbf{1}_\zeta). \quad (1)$$

Here, the integral extends over the volume of the system, $\mathbf{1}_\zeta$ denotes the unit vector in the ζ^{th} Cartesian direction, and the coarse graining function, $\Phi_k(x)$, must be normalized, i.e., $1 = \sum_k \Phi_k(x)$. The particular function that we have chosen to use is

$$\Phi_k(x) = \int dy \phi(x-y) \left[h_k(x)h_k(y) + h_{k+1}(x) \sum_{j \leq k} h_j(y) + h_{k-1}(x) \sum_{j \geq k} h_j(y) \right] \quad (2)$$

where

$$\phi(x) = (2\pi\sigma^2)^{-1/2} \exp(-x^2/2\sigma^2), \quad (3)$$

$\sigma = 1\text{Å}$, and $h_k(x)$ is unity when x is in the k^{th} interval and zero otherwise. Since $\Phi_k(x)$ is normalized, $\sum_{\mathbf{k}} P_{\mathbf{k}} = N$ is the total number of water molecules. In effect, this choice spreads the atomistic density field $\rho(\mathbf{r})$ over the lengthscale σ and bins it into a grid of lengthscale l in such a way as to preserve normalization. While we have found this choice of coarse graining function to be convenient, others are possible.

Figs. 1A and B illustrate the coarse-graining procedure. In part A, the solvent is schematically shown before and after coarse-graining. In part B, the same mapping is shown for the actual system considered herein. Cells are shaded white when their solvent occupation, $P_{\mathbf{k}}$, is less than half of its bulk average value of $\langle P \rangle_{\text{bulk}} \equiv c = 0.3$ molecules. Small local density fluctuations are seen throughout the simulation box, as is expected for an instantaneous solvent configuration.

In addition to visualizing solvent density, the coarse-graining algorithm is useful for controlling the solvent density in MD simulations. For example, if it is desired that a particular cell $\mathbf{k}$ exhibit a solvent occupation $P_{\mathbf{k}}^*$,

FIG. 1: (A) The coarse-graining procedure is schematically shown to project the atomistic solvent density onto a discrete grid. (B) The same procedure is shown for an instantaneous solvent configuration of the actual system. Grid cells containing less solvent density than $c/2$ are colored white; the remaining cells are left transparent against the blue background. The hydrophobic chain is shown in red. (C) The potential in Eq. 4 is used to restrain atomistic solvent density to the reference distribution at the far left. With larger κ , reported numerically in units of $2k_B T/c^2$, the average atomic solvent density reproduces the reference distribution in detail (see text for notation).

the following potential energy term can be used to derive the appropriate forces on the atoms in the simulation,

$$\frac{1}{2}\kappa(P_{\mathbf{k}} - P_{\mathbf{k}}^*)^2, \quad (4)$$

where κ is an appropriate force constant. This technique is illustrated in Fig. 1C. The left-most panel shows a density distribution that is exceedingly unlikely for a simulation of ambient liquid water. Panels to the right show the average solvent density distribution from MD simulations that are restrained to this unlikely reference distribution with increasing κ . Force constant values greater than $2k_B T/c^2$, in which the simulation incurs an energetic penalty of at least $k_B T$ for placing the average bulk density in a cell that is restrained to be empty, ensure that the reference distribution is recovered in detail.

C. String method in collective variables

We use the string method in collective variables to calculate the minimum free energy path (MFEP) for the

collapse of the hydrated chain.^{1,2,3} To explain, we introduce some notation. Let $\mathbf{x} = (\mathbf{x}_c, \mathbf{w})$ be the position vector of length $n = 3 \times 12 + 3 \times 3 \times N$ for the atomistic representation of the entire system, where $\mathbf{x}_c$ is the position vector for the atoms in the chain, and $\mathbf{w}$ is the position vector for the atoms in the water molecules. Similarly, let $\mathbf{z}(\mathbf{x}) = (\mathbf{x}_c, \mathbf{P})$ be the vector of length $\mathcal{N} = 3 \times 12 + 48 \times 48 \times 56$ for the collective variable representation of the system, where the elements of $\mathbf{P}$ are defined in Eq. 1.

The MFEP, $\mathbf{z}^*(\alpha)$, is parameterized by the string coordinate α , where $\alpha = 0$ corresponds to the collapsed chain and $\alpha = 1$ corresponds to the extended chain. It obeys the condition

$$\frac{dz_i^*(\alpha)}{d\alpha} \text{ parallel to } \sum_{j=1}^{\mathcal{N}} M_{ij}(\mathbf{z}^*(\alpha)) \frac{\partial F(\mathbf{z}^*(\alpha))}{\partial z_j}, \quad (5)$$

where

$$F(\mathbf{z}) = -\beta^{-1} \ln \left\langle \prod_{i=1}^{\mathcal{N}} \delta(z_i - z_i(\mathbf{x})) \right\rangle \quad (6)$$

is the free energy surface defined in the collective variables, and

$$M_{ij}(\mathbf{z}) = \exp[\beta F(\mathbf{z})] \times \left\langle \sum_{k=1}^n m_k^{-1} \frac{\partial z_i(\mathbf{x})}{\partial x_k} \frac{\partial z_j(\mathbf{x})}{\partial x_k} \prod_{i=1}^{\mathcal{N}} \delta(z_i - z_i(\mathbf{x})) \right\rangle. \quad (7)$$

Here, angle brackets indicate equilibrium expectation values, $\beta = (k_B T)^{-1}$ is the reciprocal temperature, and m_k is the mass of the atom corresponding to coordinate x_k .

If the employed collective variables are adequate to describe the mechanism of the reaction (here, the hydrophobic collapse), then it can be shown that the MFEP is the path of maximum likelihood for reactive MD trajectories that are monitored in the collective variables.³ In the current application, we shall check the adequacy of the collective variables *a posteriori* by running MD trajectories that are initiated from the presumed rate-limiting step along the MFEP (i.e. the configuration of maximum free energy) and verifying that these trajectories lead with approximately equal probability to either the collapsed or extended configurations of the chain (see Section III C).

The string method yields the MFEP by evolving a parameterized curve (i.e. a string) according to the dynamics^{3,16}

$$\begin{aligned} \frac{\partial z_i^*(\alpha, t)}{\partial t} = & - \sum_{j=1}^{\mathcal{N}} M_{ij}(\mathbf{z}^*(\alpha, t)) \frac{\partial F(\mathbf{z}^*(\alpha, t))}{\partial z_j} \\ & + \lambda(\alpha, t) \frac{\partial z_i^*(\alpha, t)}{\partial \alpha} \end{aligned} \quad (8)$$

where the term $\lambda(\alpha, t) \partial z_i^*(\alpha, t) / \partial \alpha$ enforces the constraint that the string remain parameterized by normalized arc-length. The endpoints of the string evolve by

steepest decent on the free energy surface,

$$\frac{\partial z_i^*(\alpha, t)}{\partial t} = -\frac{\partial F(\mathbf{z}^*(\alpha, t))}{\partial z_i}, \quad (9)$$

for $\alpha = 0$ and $\alpha = 1$. These artificial dynamics of the string yield the MFEP, which satisfies Eq. 5.

In practice, the string is discretized using N_d configurations of the system in the collective variable representation. The dynamics in Eqs. 8 and 9 are then accomplished in a three-step cycle where (i) the endpoint configurations of the string are evolved according to Eq. 9 and the rest of the configurations are evolved according to the first term in Eq. 8, (ii) the string is (optionally) smoothed, and (iii) the string is reparameterized to maintain equidistance of the configurations in the discretization. Step (i) requires evaluation of the mean force elements $\partial F(\mathbf{z})/\partial z_i$ and the tensor elements $M_{ij}(\mathbf{z})$ at each configuration. These terms are obtained using restrained atomistic MD simulations of the sort illustrated for the solvent degrees of freedom in Fig. 1C. The details of the string calculation are provided in Supporting Information Sec. B.

III. HYDROPHOBIC COLLAPSE OF A HYDRATED CHAIN

A. Minimum free energy path

Fig. 2 shows the MFEP for the hydrophobic collapse of the hydrated chain. It is obtained using the string method in the collective variables for the chain atom positions and the grid-based solvent density field. The string is discretized using $N_d = 40$ configurations of the system, and it is evolved using the steepest descent dynamics in Eqs. 8 and 9 to yield the MFEP that satisfies Eq. 5. The free energy profile is obtained by integrating the projection of the mean force along the MFEP, using

$$F^*(\alpha) = \int_0^\alpha \nabla F(\mathbf{z}^*(\alpha')) \cdot d\mathbf{z}^*(\alpha'). \quad (10)$$

Upon discretization, $s = N_d \times \alpha$ is the configuration number that indexes the MFEP. The resolution of $F^*(\alpha)$ in Fig. 2 could be improved by employing a larger N_d , but at larger computational cost.

To the extent that the collective variables employed in this study adequately describe the mechanism of hydrophobic collapse, the variable s parameterizes the reaction coordinate for the collapse dynamics; this assumption is checked below with the use of straightforward MD simulations. The statistical errors in the free energy profile between consecutive configurations are approximately the size of the plotted circles, and the small features in the profile at configurations 27 and 31 are due to noise in the convergence of the string calculation. The lower panel of Fig. 2 presents configurations along the MFEP in the region of the free energy barrier. As in Fig. 1,

FIG. 2: The minimum free energy path obtained using the string method. Above, the free energy profile exhibits a single peak at configuration 22. Below, the configurations of the path in the vicinity of the free energy peak are shown with configuration numbers indicated in white text.

lattice cells with less than half of the bulk solvent occupation number fade to white.

The free energy profile in Fig. 2 is dominated by a single barrier at configuration 22, where a liquid-vapor interface is formed at a bend in the hydrophobic chain. The sharply curved chain geometry presents an extended hydrophobic surface to molecules located in the crook of the bend, an environment that is analogous to that experienced by water trapped between hydrophobic plates and known to stabilize large-lengthscale solvent density fluctuations.^{17,18,19} The barrier in the calculated free energy profile clearly coincides with a collective motion in the solvent variables.

B. The solvation free energy

A simple theory can be constructed to understand the contributions to the free energy profile in Fig. 2 and to test the validity of coarse-graining solvent interactions. Noting that our choice of collective variables for the string calculation neglects the configurational entropy of the chain, the free energy profile F can be decomposed into the configurational potential energy of the chain E_c

and the free energy of hydrating the chain F_h ,

$$F^*(\alpha) = E_c(\alpha) + F_h(\alpha). \quad (11)$$

The term $E_c(\alpha)$ is easily evaluated from the chain potential energy term, yielding the components of the free energy profile shown in Fig. 3A.

We focus our attention on F_h . The solvation free energy for hydrophobes of idealized geometry is well understood. For small-lengthscale hydrophobes (< 1 nm), this energy scales linearly with the solute volume, whereas for large-lengthscale hydrophobes, it scales linearly with the solute surface area.^{17,20} But theoretical prediction of the solvation free energy for more complicated solute geometries is not necessarily trivial. For example, depending on its configuration, some parts of the chain considered here might be solvated like a large-lengthscale hydrophobe, whereas other parts might behave like a small-lengthscale hydrophobe.

We have developed a technique for parsing a general hydrophobic solute into components that belong to either the small-lengthscale or large-lengthscale regimes. We define the solvent-depleted volume as the continuous set of lattice cells that are, on average, occupied by less than 50% of the average bulk solvent value (this set includes both the volume that is excluded by the hard-sphere-like interactions between the solute and solvent interactions, as well as any additional volume in the vicinity of the solute that is not substantially occupied by the solvent). We also introduce a probe volume that is a cubic $4 \times 4 \times 4$ set of cells, which is approximately the size at which the water solvation structure changes from the small-lengthscale to the large-lengthscale regime.

The probe volume is used to determine whether a given section of the solvent-depleted volume is in the small- or large-lengthscale regime. This is done by moving the probe volume throughout the simulation box and determining whether it can be fit into different portions of the solvent-depleted volume. If, at a given position, the vast majority of this probe volume (specifically 59 out of 64 cells) fits within the solvent-depleted volume, then the cells in that portion of the solvent-depleted volume are included in the large-lengthscale component, V_{col} . Portions of the solvent-depleted volume that do not meet this criterion for any position of the probe volume are included in the small-lengthscale component, V_{ext} . The volumes V_{col} and V_{ext} , which are plotted in Fig. 3B, primarily include contributions from the collapsed portions and extended portions of the chain, respectively. The total volume V_{tot} is obtained by counting the total number of cells in the solvent-depleted volume, such that $V_{tot} = V_{ext} + V_{col}$.

The total surface area, A_{tot} , and its large-lengthscale component, A_{col} , were obtained by counting the number of external faces on the cells that comprise V_{tot} and V_{col} , respectively. The surface area of the small-lengthscale component was obtained using $A_{ext} = A_{tot} - A_{col}$. To account for the fact that we are calculating the area of a smooth surface by projecting it onto a cubic lattice, each

FIG. 3: A simple theory describes the solvation free energy of irregular hydrophobic solute geometries. (A) The calculated free energy profile F^* is decomposed into contributions from the chain configurational potential energy E_c and the free energy of solvation F_h . (B) The volume of the hydrated chain is parsed into large-lengthscale (V_{col}) and small-lengthscale (V_{ext}) components. (C) The surface area of the chain is similarly parsed. (D) The dotted line indicates the solvation free energy obtained using a relation (Eq. 12) that is based on the volume-scaling of the small-lengthscale solvation free energy and the surface area-scaling of the large-lengthscale solvation free energy. The solvation free energy obtained from simulation (solid line) is included for comparison.

surface area term was also multiplied by a $2/3$, a correction factor that is exact for an infinitely large sphere. The surface area components are plotted in Fig. 3C.

We use the parsed components of the solute volume and surface area to estimate the solvation free energy for the chain along the minimum free energy path with the relationship

$$F_h(\alpha) = \lambda V_{\text{ext}}(\alpha) + \gamma A_{\text{col}}(\alpha). \quad (12)$$

The coefficients λ and γ are, respectively, the prefactors for the linear scaling of the solvation free energy in the small-lengthscale and large-lengthscale regimes, as obtained by calculations on a spherical hydrophobic solute.²⁰ Their values are taken to be $\lambda = 8 \text{ mJ}/(\text{m}^2 \text{ \AA})$ and $\gamma = 45 \text{ mJ}/\text{m}^2$.

The results of this calculation are presented in Fig. 3D. The dotted line indicates our theoretical estimate of the solvation free energy using Eq. 12, and the solid line indicates the data from the atomistic simulations (from Fig. 3A). The agreement is very good, and as is shown in Supporting Information Sec. C, it is better than can be obtained from solvation free energy estimates that exclusively consider either the solute volume or the solute surface area. This result demonstrates that atomistic solvent energetics can be quantitatively modeled using a grid-based solvent density field. Furthermore, we note in Fig. 3B and C that the collapsing chain first develops large-lengthscale components in the vicinity of the peak in the free energy profile, which suggests that this peak coincides with the crossover from small- to large-lengthscale solvation (i.e. dewetting). This observation is consistent with the collective solvent density motion that is observed near the free energy barrier in Fig. 2.

C. The committor function and a proof of principle for coarse graining

The various assumptions that are employed in our implementation of the string method, including our choice of collective variables and the corresponding neglect of the chain configurational entropy, raise the possibility that the barrier in the free energy profile in Fig. 2 does not correspond to the dynamical bottleneck for hydrophobic collapse. This is a general concern in trying to relate free energy calculations to dynamical quantities, such as the reaction mechanism and the reaction rate. To confirm that the calculated free energy profile is dynamically relevant, we evaluate the committor function at several configurations along the MFEP. The committor function reports the relative probability that MD trajectories that are initialized from a particular collective variable configuration first proceed to the extended configurations of the chain, as opposed to the collapsed configurations. For initial collective variable configurations that coincide with the true dynamical bottleneck, the committor function assumes a value of exactly 0.5.

We first evaluate the committor function at configuration 22, which corresponds to the peak in the calculated free energy profile in Fig. 2. The committor function is obtained by performing straightforward MD trajectories from initial conditions that are consistent with this collective variable configuration, and then tallying the fraction of those trajectories whose endpoints are “extended,” as opposed to “collapsed”. The initial conditions for these trajectories are obtained from a 20 ps MD trajectory that is restrained to the collective variables for configuration 22; the atomistic coordinates of the restrained trajectory are recorded every picosecond. From each set of atomistic coordinates, an unrestrained trajectory was run for 150 ps forwards and backwards in time with the initial atomistic velocity vector drawn from the Maxwell-Boltzmann distribution at 300 K. To decide whether a given unrestrained trajectory terminates in either an extended or collapsed configuration of the chain, we employ an order parameter based on the number of chain atoms that are within $1.25 \text{ \AA}$ of another chain atom to which it is not directly bonded. If the number of non-bonded contacts exceeds three, the chain is considered to be in a collapsed configuration; otherwise it is considered extended. This order parameter need only distinguish between collapsed and extended configurations of the chain; it need not be (and in fact is not) a good reaction coordinate. Fig. 4 illustrates representative forward and backwards unrestrained MD trajectories.

The committor function at configuration 22 is 0.3 ± 0.1 , suggesting that the calculated free energy barrier is slightly biased towards the basin of stability for the collapse chain. However, this deviation from the ideal value of 0.5 is only marginally statistically significant, and we emphasize that the committor function is exponentially sensitive in the region of the dynamical bottleneck. To illustrate this point, we repeat the evaluation of the committor function at configuration 20, which is seen in Fig. 2 to be near the barrier peak but slightly closer to the collapsed configurations of the chain, as well as at configuration 24, which is slightly closer to the extended configurations. We find the committor function at configuration 20 to be 0.00 ± 0.05 and the value at configuration 24 to be 0.90 ± 0.05 . Only very minor shifts along the MFEP dramatically change the value of the committor function.

Given the extreme sensitivity of the committor function near the dynamical bottleneck, the fact that configuration 22 gives rise to a significant fraction of trajectories that proceed to both the collapsed and extended basins is very significant. Furthermore, the direction in which the committor function changes as a function of the configuration number is as is expected in the vicinity of the dynamical bottleneck. We conclude that the barrier in the calculated free energy profile correctly characterizes the true free energy barrier - thus identifying the rate-limiting step for the collapse dynamics.

The committor function calculations, which are based on straightforward MD simulations, indicate that our

FIG. 4: Snapshots from unrestrained MD trajectories that are initiated from the calculated free energy barrier at configuration 22. The instantaneous atomistic configurations are visualized in the collective variable representation, using the same technique that was introduced in Figs. 1 A and B.

choice of collective variables provides a reasonable description of the mechanism of hydrophobic collapse. This result yields atomistic support for the strategy of coarse-graining solvent dynamics. Using (i) that it is straightforward³ to obtain the stochastic dynamics in the collective variables for which the most likely reaction pathway is the same as the mechanism obtained using the string method and (ii) that the mechanism for hydrophobic collapse obtained in the employed collective variables agrees with the mechanism obtained using atomistic dynamics, we obtain a proof of principle that atomistic solvent dynamics can be usefully projected onto a coarse-grained field.

The coarse-grained dynamics obtained via this argument are³

$$\begin{aligned} \bar{\gamma} \frac{\partial z(t)}{\partial t} = & - \sum_{j=1}^{\mathcal{N}} \left(M_{ij}(\mathbf{z}(t)) \frac{\partial F(z(t))}{\partial z_j} - \beta^{-1} \frac{\partial M_{ij}(z(t))}{\partial z_j} \right) \\ & + \sqrt{2\beta^{-1}\bar{\gamma}} \sum_{j=1}^{\mathcal{N}} M_{ij}^{1/2}(z(t)) \eta_j(t), \end{aligned} \quad (13)$$

where $\eta_i(t)$ is a white noise satisfying $\langle \eta_i(t) \eta_j(t') \rangle = \delta_{ij} \delta(t - t')$ and t is an artificial time that is scaled by the friction coefficient $\bar{\gamma}$. The computational feasibility of directly integrating these coarse-grained dynam-

ics, however, hinges on the cost of calculating the mean force elements $\partial F(\mathbf{z})/\partial z_j$ and the tensor elements $M_{ij}(\mathbf{z})$ and $\partial M_{ij}(\mathbf{z})/\partial z_j$, since these terms are required at every coarse-grained timestep. It is thus encouraging that the free energy surface in the collective variables can be quantitatively modeled in lieu of atomistic simulations, by using Eqs. 11 and 12. Similar approximations for the tensor elements might also be possible.

D. The rate-limiting step

Using the calculated MFEP and committor function values, we have established that the rate-limiting step for the hydrophobic collapse of the hydrated chain coincides with a collective solvent motion. Using a simple analysis of the solvation free energy, we find that this collective solvent motion is consistent with lengthscale-dependent dewetting. However, it remains to be shown whether the rate-limiting step involves performing work in the solvent, or in the chain, degrees of freedom. This is an important distinction. If the latter case is true, then dewetting merely accompanies hydrophobic collapse as a spectator. But if the former case is true, then dewetting is the rate-limiting step to hydrophobic collapse.

To address this issue, we again decompose the free energy profile, this time into contributions from work performed along the solvent and the chain collective variables. The definition of the free energy profile in Eq. 10 can be written more explicitly as

$$\begin{aligned} F^*(\alpha) = & \int_0^\alpha \nabla_c F(\mathbf{z}^*(\alpha')) \cdot d\mathbf{x}_c(\alpha') \\ & + \sum_{\mathbf{k} \in V} \int_0^\alpha \nabla_{P_{\mathbf{k}}} F(\mathbf{z}^*(\alpha')) dP_{\mathbf{k}}(\alpha') \end{aligned} \quad (14)$$

where $\nabla_c F(\mathbf{z}^*(\alpha'))$ is the vector of mean forces acting on the chain atom positions at configuration $s = N_d \times \alpha$ along the MFEP, and $\nabla_{P_{\mathbf{k}}} F(\mathbf{z}^*(\alpha'))$ is the corresponding mean force on the solvent collective variable $P_{\mathbf{k}}$. The full free energy profile is obtained by setting the volume V equal to the entire simulation box. But to understand the role of solvent in hydrophobic collapse, it is informative to calculate the free energy profile using various smaller solvent volumes.

The bottom curve in Fig. 5 is obtained from Eq. 14 by letting V be the empty set, thus eliminating the second term. The middle curve is obtained by letting V be the set of $8 \times 8 \times 8$ lattice cells at the middle of the simulation box, as is indicated in the corresponding image, and the top curve is obtained by letting V be the middle set of $20 \times 20 \times 20$ lattice cells. Consideration of larger sets of lattice cells does not further alter the free energy profile, as is shown in Supporting Information Sec. D. The solvent variables for regions of space that are distant from the collapsing chain remain constant along the path and do not contribute to the free energy profile.

FIG. 5: The free energy profile from Fig. 2 is separated into contributions from the chain and solvent coordinates. In the bottom curve, only the first term in Eq. 14, which corresponds to work performed in the chain coordinates, is included in the free energy profile. In the middle and top curves, solvent contributions are also included. The solvent volume included for each curve is indicated with a wire box. Inclusion of larger solvent volumes does not substantially change the profile.

The bottom curve in Fig. 5 only shows the work performed on the chain atom positions during hydrophobic collapse. Remarkably, it lacks almost any free energy barrier, indicating that essentially no work is performed in the chain degrees of freedom in crossing the dynamical bottleneck. Instead, we see that the barrier emerges only upon inclusion of the work performed in the solvent collective variables. Performing the hydrophobic collapse involves traversing a free energy barrier that exists only in the solvent coordinates. This figure shows that the dewetting transition not only accompanies the rate-limiting step for hydrophobic collapse, but that it is the rate-limiting step.

SUPPORTING INFORMATION

A. Details of the system

We consider a hydrophobic chain in explicit solvent. The unbranched chain is composed of $N_s = 12$ spherical atoms of diameter $7.2 \text{ \AA}$ and mass 70.73 amu . The interactions between the chain atoms were treated with the purely repulsive WCA potential ($\sigma = 6.4145 \text{ \AA}$, $\epsilon = 15 \text{ kJ/mol}$), which provides a slightly softened hard-sphere interaction that is convenient for molecular dynamics (MD) simulations. Neighboring atoms are linked by harmonic bonds, using

$$V_{\text{bond}} = \sum_{k=1}^{N_s-1} \frac{1}{2} k_b (l_b - |\mathbf{r}_{k+1} - \mathbf{r}_k|)^2, \quad (15)$$

where $|\mathbf{r}_{k+1} - \mathbf{r}_k|$ is the distance between chain atoms at positions $\mathbf{r}_k$ and $\mathbf{r}_{k+1}$, $l_b = 7.2 \text{ \AA}$, and $k_b = 84.9102 \text{ kJ/mol/\AA}^2$. To add some rigidity to the chain, a harmonic potential is included to penalize its curvature,

$$V_{\text{angle}} = \sum_{k=2}^{N_s-1} \frac{1}{2} k_\phi \phi_k^2, \quad (16)$$

where ϕ_k is the angle between neighboring bond vectors $(\mathbf{r}_{k+1} - \mathbf{r}_k)$ and $(\mathbf{r}_k - \mathbf{r}_{k-1})$, and $k_\phi = 11.1407 \text{ kJ/mol/radian}^2$.

The chain was solvated with 33,912 water molecules in an orthorhombic simulation cell with periodic boundary conditions and dimensions of $99.5 \text{ \AA} \times 99.5 \text{ \AA} \times 116.1 \text{ \AA}$. Interactions among water molecules are described with the SPC/E rigid water potential,¹ and the chain atoms interact with the oxygen atoms in the water molecules via WCA repulsions^{2,3,4,5} ($\sigma = 4.617 \text{ \AA}$, $\epsilon = 10 \text{ kJ/mol}$). All MD simulations were performed at 300 K using the Nosé-Hoover thermostat and a timestep of 2 fs.⁶ Constant pressure conditions were maintained in the simulations using the liquid-vapor coexistence technique described in the text. To ensure that the liquid-vapor interface remains flat, as opposed to collapsing under the surface tension of the liquid, the solvent density restraint potential in Eq. 4 was applied to the top two layers of lattice cells in the simulation box with parameters $P_k^* = 0$ and $\kappa = 100 \text{ kJ/mol/molecule}^2$. All MD calculations were performed using a modified version of the DL-POLY-3 molecular simulation package.⁷

B. String method in collective variables

The string method^{8,9,10} is a technique for calculating the committor function for a dynamical process. The constant-value contours of the committor function are approximated by a collection of hyperplanes that are perpendicular to a given path (the string). This approximation can be justified within the framework of transition

path theory (TPT),¹¹ which yields a variational criterion for the string such that the perpendicular hyperplanes optimally approximate the isocommittor surfaces.

The string method in collective variables characterizes the committor function projected onto the space of collective variables. Provided that the collective variables adequately describe the reaction and that the reactive trajectories projected onto the space of collective variables remain confined to a relatively narrow tube, the approximation is not only optimal but also accurate. In this case, it can be shown that the string coincides with the minimum free energy path (MFEP) in the space of collective variables, which is also the path of maximum likelihood for the reaction monitored in these variables.

Unlike other free-energy mapping techniques, the string method focuses only on a linear subset of the space of collective variables. It thus scales independently of the dimensionality of the full free energy surface. The method does not require performance of long, reactive MD trajectories. Instead, a double-ended approach is employed in which the path is updated using short, restrained MD simulations.

A complete discussion of the implementation of the string method in collective variables can be found in Ref. 10. We represent the string in the variables of the chain atom positions and the solvent cell densities, as is explained in the primary text. Data needed for the calculation of the minimum free energy path were obtained from restrained MD simulations,

$$\frac{\partial F(\mathbf{z})}{\partial z_i} = \lim_{\kappa \rightarrow \infty} \kappa \int_{\mathbb{R}^n} (z_i - z_i(\mathbf{x})) \rho_{\kappa,z}(\mathbf{x}) d\mathbf{x} \quad (17)$$

and

$$M_{ij}(\mathbf{z}) = \lim_{\kappa \rightarrow \infty} \int_{\mathbb{R}^n} \sum_{k=1}^n m_k^{-1} \frac{\partial z_i(\mathbf{x})}{\partial x_k} \frac{\partial z_j(\mathbf{x})}{\partial x_k} \rho_{\kappa,z}(\mathbf{x}) d\mathbf{x}, \quad (18)$$

where

$$\rho_{\kappa,z}(\mathbf{x}) = \exp(-\beta U_{\kappa,z}(\mathbf{x})) / Z_{\kappa,z}, \quad (19)$$

$$Z_{\kappa,z} = \int_{\mathbb{R}^n} \exp(-\beta U_{\kappa,z}(\mathbf{x})) d\mathbf{x}, \quad (20)$$

$$\text{and } U_{\kappa,z}(\mathbf{x}) = V(\mathbf{x}) + \frac{\kappa}{2} \sum_{i=1}^N (z_i - z_i(\mathbf{x}))^2. \quad (21)$$

The string is converged to the MFEP using Eqs. 8 and 9. Between timesteps of these dynamics, the string is smoothed and reparameterized. The smoothing procedure is performed using

$$\mathbf{z}^{m,*} = (1 - \eta) \mathbf{z}^m + \frac{\eta}{2} (\mathbf{z}^{m-1} + \mathbf{z}^{m+1}), \quad (22)$$

where $\mathbf{z}^{m,*}$ and $\mathbf{z}^m$ indicate the m^{th} configuration of the smoothed and unsmoothed string, respectively. The parameter $\eta = 0.05$ was chosen to be sufficiently small ($O(N_d^{-1})$), as is discussed in Ref. 10) that the smoothing

procedure does not effect the accuracy of the calculated MFEP. Reparameterization of the string was performed using the linear interpolation scheme described in Ref. 10.

The string was initialized from configurations of an MD trajectory in which the hydrated chain was artificially extended from a collapsed configuration with the aid of a greatly magnified force constant in the chain potential energy term V_{angle} . In the first stage of the string calculation, the string was discretized using 20 configurations and evolved using large timesteps and weak collective variable restraints. Specifically, we employed chain atom restraint force constants of 2 kJ/mol/Å², solvent restraints of 10 kJ/mol/molecule², and a steepest descent timestep of 300 fs. Restrained MD trajectories of 10 ps were performed during this stage. This first stage of the string calculation included nine steepest descent timesteps.

In a second stage of the string calculation, the number of images used to represent the path was increased to 40, the chain atom restraints were increased to 5 kJ/mol/Å², the solvent restraints were increased to 40 kJ/mol/molecule², the steepest descent timestep was decreased to 40 fs, and the restrained MD trajectory time was increased to 20 ps. The second stage of the string calculation was terminated after six optimization steps, at which point reasonable convergence, as determined by monitoring changes in the path and its corresponding free energy profile, was obtained. Throughout both stages of the string calculation, the path endpoint image corresponding to the extended configuration was (after local relaxation) held fixed, and the other endpoint corresponding to the collapsed chain was allowed to relax on the free energy surface according to Eq. 9. The final, converged string bears little resemblance to the initial guess.

The string method is a local, rather than global, optimization scheme. Different minimized free energy paths might have been obtained from string calculations started with different initial paths. However, the simple topology of the chain, as well as the unrestrained MD simulations presented in the paper, suggest that the calculated MFEP is a reasonable characterization of the reaction mechanism for the hydrophobic collapse of the hydrated chain.

All computations were performed in parallel using 2.2 GHz AMD Operton processors. Each step in the first of the stage of the string calculation required 600 CPU hours. Each step in the second stage required 2400 CPU hours. Each evaluation of the committor function described in Sec. IIIC required 15,000 CPU hours.

C. Alternative models for the solvation free energy

Even with the aide of a one-parameter fit, the solvation free energy profiles estimated on the basis of only solvent-depleted surface area or only solvent-depleted volume do

FIG. 6: (Supporting Information) Alternative models for the solvation free energy. The profile obtained from simulation is shown as a solid line, and that obtained using Eq. 12 is shown as a dotted line. In Panel A, the dot-dashed line indicates the solvation free energy profile obtained from consideration of only the chain surface area, using Eq. 23. In Panel B, the dot-dashed line indicates the solvation free energy profile obtained from consideration of only the chain volume, using Eq. 24.

not match the accuracy obtained using Eq. 12 in the text. In Fig. 6A, we see the profile (dot-dashed line) obtained by fitting $\tilde{\gamma}$ in the expression

$$F_h(\alpha) = \tilde{\gamma} A_{\text{tot}}(\alpha). \quad (23)$$

The height of the shoulder at configurations 14-18 and the barrier peak region do not reproduce the simulated results (solid line) as well as Eq. 12 (dotted line). As is seen Fig. 6B, the solvation free energy profile (dot-dashed) that is obtained using the expression

$$F_h(\alpha) = \tilde{\lambda} V_{\text{tot}}(\alpha) \quad (24)$$

is less accurate than that obtained using either Eqs. 12 or 23.

FIG. 7: (Supporting Information) Free energy profiles for the MFEP, calculated using Eq. 14 with V equal to the middle $b \times b \times b$ lattice cells of the simulation box.

D. Convergence of the free energy profile with increasing solvent box sizes

We show that the free energy profile calculated using Eq. 14 converges with respect to the solvent contribution. The curves in Fig. 7 correspond to free energy profiles obtained with V equal to the middle $b \times b \times b$ lattice cells of the simulation box. The profile changes dramatically with b until V fully encompasses the region of the bending chain, where the dewetting transition occurs. For $b > 16$, no major changes are seen in the profile, since the added contributions are from solvent cells that are distant from the collapsing chain. The small changes that are found with large b are due to statistical noise. This noise increases with larger b since the number of included solvent cells increases as b^3 .
